A. Probabilistic Face Parameterization

A.1. Multilinear Face Representation

In this paper, we collect the \( N_{id} \times N_{exp} = 150 \times 47 \) blendshapes to form the multilinear face representation, as suggested by Cao et al. [1]. Provided the shape dimension \( N_M \times 3 = 11510 \times 3 \), the dataset forms a tensor \( D \in \mathbb{R}^{N_M \times N_{id} \times N_{exp}} \). By subtracting \( D \) with the mean face mesh \( \bar{f} \), the applied data tensor is \( T = D - \bar{f} \).

The multilinear face representation requires the unary matrices \( U_{id} \) and \( U_{exp} \), which can be derived from Higher-order SVD (HOSVD) with respect to the second and third dimensions for identity and expression, respectively. The core tensor is thus \( C = T \times_2 U_{id} \times_3 U_{exp} \), and inversely the data tensor can be derived as \( T = C \times_2 U_{id}^\top \times_3 U_{exp}^\top \). Therefore, one face can be represented by linear combination of the data tensor with respect to the identity \( x_{id} \in \mathbb{R}^{N_{id}} \) and expressions \( x_{exp} \in \mathbb{R}^{N_{exp}} \), together with the mean face model

\[
\bar{f} = \bar{f} + C \times_2 U_{id} \times_3 x_{id} \times_3 x_{exp}
\]

\[
= \bar{f} + C \times_2 (U_{id}^\top x_{id}) \times_3 (U_{exp}^\top x_{exp})
\]

\[
= \bar{f} + C \times_2 w_{id} \times_3 w_{exp}^\top.
\]

\( w_{id} \) and \( w_{exp} \) are the parameters employed in this paper.

A.2. Learning the Identity and Expression Priors

Each face mesh in the training dataset is assigned a one-hot label vector for identity \( x_{id} \) and one for expression \( x_{exp} \). For example, the face mesh with the neutral expression from the first subject has \( x_{id} = [1, 0, \ldots, 0]^\top \in \mathbb{R}^{N_{id}} \) and \( x_{exp} = [1, 0, \ldots, 0]^\top \in \mathbb{R}^{N_{exp}} \).

Therefore, the mean face model \( \bar{f} \) has \( x_{id} = \frac{1}{N_{id}} - 1 \) and \( x_{exp} = \frac{1}{N_{exp}} - 1 \). The identity has \( \text{Var}(x_{id}) = \frac{1}{N_{id}} I - \frac{1}{N_{id}^2} I \simeq \frac{1}{N_{id}} I \), where \( I \) is the identity matrix and \( I \) is the matrix filled by one. Similarly, \( \text{Var}(x_{exp}) = \frac{1}{N_{exp}} I \). The mean and variance of \( w_{id} \) and \( w_{exp} \) are thus

\[
\mu_{id} = \frac{1}{N_{id}} U_{id} \mathbf{1}, \quad \Sigma_{id} \simeq \frac{1}{N_{id}} U_{id} U_{id}^\top = \frac{1}{N_{id}} I
\]

\[
\mu_{exp} = \frac{1}{N_{exp}} U_{exp} \mathbf{1}, \quad \Sigma_{exp} \simeq \frac{1}{N_{exp}} U_{exp} U_{exp}^\top = \frac{1}{N_{exp}} I.
\]

We also observe that the mean face \( \bar{f} \) corresponds to \( x_{id} \) and \( x_{exp} \), thus it results in

\[
|| \mathcal{T} \times_2 x_{id} \times_3 x_{exp} ||^2 = || C \times_2 \mu_{id} \times_3 \mu_{exp}^\top ||^2
\]

\[
\simeq || \bar{f} \times_3 \bar{f}^\top ||^2 = 0
\]

\[
= \mu_M \simeq \bar{f},
\]

which means these priors will not bias the face model representations.

We need to mention that \( \mu_{id} \) and \( \mu_{exp} \) should not be zero vectors. If we assume that \( \mu_{id} = 0 \), it will result in the independence of the face model with respect to the varying of the expression parameters, i.e., \( C \times_2 w_{id} \times_3 w_{exp} \simeq 0 \) in which the \( w_{id} \) is usually near to the zero vector. The same problem happens when \( \mu_{exp} = 0 \). What’s worse, such priors lead to unstable solutions, i.e., \( C \times_3 w_{exp} \) suffers such a small magnitude that the online adaptation system (derived from section 4.2) with respect to \( w_{id} \) will be unstable.

B. Probabilistic Facial Pose Tracking

B.1. Ray Visibility Score

The ray visibility score is the Kullback-Leibler divergence between \( p_P(y) \) and \( p_Q \rightarrow P(y; \theta) \), written as:

\[
S(Q, P; \theta) = D_{KL}[p_Q \rightarrow P(y; \theta)||p_P(y)]
\]

\[
= \sum_{n=1}^{N_M} D_{KL}[p_Q \rightarrow P(y_n; \theta)||p_P(y_n)],
\]
where \( D_{KL} [p_{Q} \rightarrow p_{P}(y; \theta) | | p_{P}(y_n)] \) is further derived as

\[
\frac{\gamma_n}{2\sigma_n^2} \left\{ \sigma_o^2 + e^{2\alpha_n^T \Sigma_n^{(\omega)} n_n + \Delta(T(\theta) \circ \mu_{M,[n]}; p_n)^2} \right\} + \frac{\gamma_n}{2} \left\{ \log 2\pi + \log \sigma_o^2 \right\} - (1 - \gamma_n) \log U_Q
\]

\[
- \frac{1}{2} \left\{ 1 + \log 2\pi + \log(\sigma_o^2 + e^{2\alpha_n^T \Sigma_n^{(\omega)} n_n}) \right\}.
\]

**B.2. Optimization of the Ray Visibility Score**

We apply the quasi-Newton update \( \theta^{(t)} = \theta^{(t-1)} + \Delta \theta \) using the trust region approach for \( S(Q, P; \theta^{(t-1)}) \) given the previous \( \gamma^{(t-1)} \), in which the key ingredient is the gradient and Hessian calculations with respect to \( \theta \). Straightforward calculation is not trivial, especially for rotation vector \( \omega \), but \( S(Q, P; \theta) \) can be written in an approximated form to reduce the complexity.

Assume we have the mean and variance for the current warped face model point \( q_n = T(\theta) \circ \mu_{M,[n]} \) and \( \Sigma_n^{(\omega)} \), we are interested in the incremental pose \( \Delta \theta \) in the ray visibility score. The incremental rotation matrix is approximated a skew-symmetric representation, \( \epsilon \omega \).

Thus \( M \), \( \theta \) in the ray visibility score can be written in an approximated form to reduce the complexity.

\[
\Delta \epsilon m_{\omega}(\Delta \omega) = (I + [\Delta \omega]_x) \epsilon m_{\omega}(\Delta \omega). 
\]

The term about the warped variance is

\[
e^{2\Delta \alpha_n^T \Sigma_n^{(\omega + \Delta \omega)} n_n} \]

\[
e^{2\Delta \alpha_n^T \Sigma_n^{(\omega + \Delta \omega)} n_n} = e^{2\Delta \alpha_n^T \Sigma_n^{(\omega + \Delta \omega)} n_n} 
\]

\[
e^{2\Delta \alpha_n^T \Sigma_n^{(\omega + \Delta \omega)} n_n} \]

and \( e^{2\Delta \alpha_n^T \Sigma_n^{(\omega + \Delta \omega)} n_n} \) are approximated quadratic forms with respect to \( \Delta \omega \), thus the gradient and Hessian calculations about the rotation vector become much simpler. The related calculations with respect to the scale factor \( \Delta \alpha \) and translation vector \( \Delta t \) involve the previous approximations and thus become simpler as well.

Moreover, to reduce the computational complexity even further, we can force the variance \( \Sigma_n^{(\omega)} = \sigma_{[n]}^{2} I \) with \( \sigma_{[n]} \) derived from the canonical face point representation. Thus \( \Sigma_n^{(\omega)} = \sigma_{[n]}^{2} I \) and \( n_n^T \Sigma_n^{(\omega)} n_n = \sigma_{[n]}^2 \) are constant with varying \( \omega \). In this case, only \( \Delta \epsilon m_{\omega}(\Delta \omega) \) makes contribution to the update of \( \omega \).

**B.3. Online Identity Adaptation**

The online identity adaptation can be progressively personalized to the test subject, as visualized in Figure 2. With different poses are used to update the identity distribution, the face model is continuously adapted to the test subject.

**C. Facial Poses with Visibility Detection**

In addition to the facial pose results visualized in the paper, we also illustrate some examples with the personalized face models, as shown in Figure 1. The proposed method can effectively check the visibility of a face model with respect to the input point cloud, and its pose estimation is robust to severe occlusions, e.g., profiled faces, accessories and hands, etc.

References

Figure 2. We continuously adapt the identities of the face model to different users. (a)-(c) are three examples showing that the face model can be gradually personalized when the facial depth data from different poses are captured during the tracking process. The face model is initialized with the generic face model.
